Abstract: Background and Objectives: Type 2 diabetes (T2D) and prediabetes represent major global health concerns, with obesity being a key risk factor. However, recent evidence suggests that the adipose tissue composition and distribution play a more critical role in metabolic dysfunction than the total body weight or body mass index (BMI). This study evaluates the predictive capacity of the Córdoba Equation for Estimating Body Fat (ECORE-BF) for identifying individuals at high risk of developing T2D and prediabetes. Materials and Methods: A cross-sectional study was carried out involving 418,343 Spanish workers. Body fat percentage was estimated using the ECORE-BF equation, and diabetes risk was assessed using validated predictive models, including the Finnish Diabetes Risk Score (FINDRISC), QDiabetes score (QD-score), and others. The discriminatory power of ECORE-BF in predicting T2D and prediabetes was assessed using receiver operating characteristic (ROC) curve analysis. Results: ECORE-BF showed a strong correlation with high-risk classifications across all diabetes risk scales. The area under the ROC curve (AUC) exceeded 0.95 for both men and women, demonstrating high predictive accuracy. Conclusions: Adipose tissue distribution, particularly visceral adiposity, is a central factor in metabolic dysfunction. ECORE-BF provides a cost-effective alternative for large-scale T2D and prediabetes risk assessment. Future research should explore the impact of visceral adipose tissue reduction on diabetes prevention and the integration of estimation scales into clinical and public health strategies.

**Keywords:** diabetes mellitus; prediabetes; visceral fat; body fat; body composition; ECORE-BF

## 1. Introduction

Diabetes mellitus is among the most common chronic non-communicable diseases, affecting millions of individuals worldwide [1]. Its increasing prevalence and significant impact on patients' quality of life have made it a critical public health concern [2]. Type 2 diabetes (T2D), responsible for approximately 90–95% of all diabetes cases worldwide, arises from a combination of insulin resistance and impaired insulin secretion by pancreatic beta cells [3–5]. The progression of the disease is influenced by multiple risk factors, including overweight, obesity [6], physical inactivity [7], and genetic predisposition [8]. Early detection [9] and proper management are essential to prevent long-term complications [10] and improve patient outcomes [11].

Type 2 diabetes has increased globally [12] and is one of the leading causes of morbidity and mortality [13]. In 2021, 537 million adults had diabetes, with projections exceeding 700 million by 2045 [14] if effective prevention and control strategies are not implemented [15]. It is more prevalent in low- and middle-income countries, where urbanization, lifestyle changes, and limited healthcare access contribute to its rise [16].

Sociodemographic factors influence the distribution of diabetes [17]. Ethnic groups such as Hispanics, African Americans, U.S. Indigenous populations [18], South Asians [19], and populations from the Middle East [20] and Africa [21] are at higher risk. Additionally, population aging increases the incidence of type 2 diabetes due to age-related insulin resistance [22].

Diabetes-related complications are broadly classified into microvascular and macrovascular complications. Microvascular complications of diabetes include retinopathy, nephropathy, and neuropathy. Retinopathy can lead to irreversible blindness [23], nephropathy is a major cause of chronic kidney disease and dialysis [24], and neuropathy increases the risk of foot ulcers and lower limb amputations due to sensory loss [25]. Macrovascular complications include cardiovascular diseases such as ischemic heart disease [26], cerebrovascular disease [27], and peripheral artery disease [28]. Hyperglycemia, dyslipidemia, and hypertension contribute to atherosclerosis [29], making cardiovascular diseases the leading cause of mortality in type 2 diabetes [30].

Early identification of individuals at high risk of developing T2D is crucial for prevention and disease management [31]. Several validated risk assessment tools have been developed to estimate the likelihood of diabetes onset in specific populations. The most widely used scales include the following:

- (1) Finnish Diabetes Risk Score (FINDRISC) [32];
- (2) American Diabetes Association (ADA) Diabetes Risk Test [33];
- (3) QDiabetes score [34].

These tools assess an individual's risk by incorporating variables such as age, body mass index (BMI), family history of diabetes, physical activity, diet, and blood pressure.

The implementation of these risk assessment tools enables the early detection of individuals in a prediabetic state [35], facilitating timely intervention strategies such as lifestyle modifications and medical follow-up. Moreover, these tools play a crucial role in shaping public health policies designed to reduce the societal burden of diabetes [36,37].

Obesity is a primary risk factor for T2D and represents a growing global public health challenge [38]. The excessive accumulation of adipose tissue, particularly in the abdominal region, is strongly linked to insulin resistance, a key pathophysiological mechanism underlying the development of T2D [39]. Visceral obesity promotes a pro-inflammatory and oxidative stress state, marked by the release of inflammatory cytokines such as tumor necrosis factor-alpha (TNF- $\alpha$ ) [40] and interleukin-6 (IL-6) [41], which impair insulin action in peripheral tissues.

Moreover, dysfunctional adipose tissue in obese individuals secretes lower levels of adiponectin, a hormone that enhances insulin sensitivity and regulates lipid and glucose metabolism. Reduced adiponectin levels, coupled with increased insulin resistance, promote chronic hyperglycemia and the progression toward T2D [42]. Additionally, obesity is associated with beta-cell dysfunction, compromising the body's ability to maintain glycemic homeostasis [43].

Epidemiological studies have demonstrated that weight reduction through lifestyle interventions, including dietary modifications and increased physical activity, can delay or prevent the onset of T2D in individuals with obesity and prediabetes [44]. In this regard, the Diabetes Prevention Program (DPP) has shown that modest weight loss (5–10% of initial body weight) can significantly reduce the risk of developing T2D [45]. Consequently, obesity prevention and treatment are critical strategies for addressing the global diabetes epidemic.

Type 2 diabetes poses a significant epidemiological burden and is associated with multiple complications. The use of validated risk assessment tools and the implementation of preventive strategies are essential to mitigate its impact. Given the strong link between obesity and T2D, it is imperative to develop effective public health policies that promote healthy lifestyles and reduce the incidence of the disease.

The objective of this study is to evaluate the utility of the Córdoba Equation for Estimating Body Fat (ECORE-BF) as a predictor of elevated values in various risk assessment scales for T2D and prediabetes.

# 2. Materials and Methods

This study is a descriptive, cross-sectional analysis conducted between January 2017 and December 2019, involving a total of 418,343 workers in Spain (246,061 men and 172,282 women) from various regions. The participants were selected from employees undergoing routine occupational health examinations in the companies that agreed to take part in this study.

To qualify for inclusion, individuals needed to be between 18 and 69 years old, employed under a contract with one of the participating companies, and not on temporary leave due to health-related reasons at the time of assessment, and they must have provided informed consent to participate in this research, allowing the collected data to be used for epidemiological analysis.

Figure 1 presents a flowchart illustrating the selection process of the employees included in this study.

Figure 1. Flowchart for selecting employees in this study.

#### 2.1. Measurement and Data Collection

Prior to data collection, this study's medical and nursing personnel standardized the measurement protocols. These healthcare professionals were responsible for conducting clinical, analytical, and anthropometric assessments, including waist circumference, weight, and height.

Height and weight measurements were obtained using a SECA 700 model weighing scale. Waist circumference was measured with SECA measuring tape while the participant stood upright, with the lower extremities together, the trunk erect, and the abdomen relaxed. The tape was positioned parallel to the floor at the level of the last floating rib to ensure accuracy.

Blood pressure readings were taken while the participant was seated, following a minimum rest period of 10 min, using a calibrated automatic sphygmomanometer (OM-RON M3). Three consecutive measurements were recorded at 60 s intervals, and the mean value was calculated.

Biochemical parameters were assessed after a fasting period of at least 12 h. Triglyceride, glucose, and total cholesterol levels were determined using automated enzymatic methods. High-density lipoprotein (HDL) cholesterol levels were measured with dextran sulfate-MgCl<sub>2</sub> precipitation techniques. Low-density lipoprotein (LDL) cholesterol was indirectly calculated using the Friedewald equation [46].

All biochemical values were reported in mg/dL. Glycemic status was classified based on the criteria established by the American Diabetes Association (ADA): fasting glucose levels below 100 mg/dL were considered normal, while values between 100 and 125 mg/dL indicated prediabetes or impaired fasting glucose, and readings exceeding 125 mg/dL were indicative of diabetes [47].

#### 2.2. Body Fat Estimation and Risk Scales

Body fat percentage was estimated using the Córdoba Equation for Estimating Body Fat (ECORE-BF), calculated as follows:

ECORE-BF = 97.102 + 0.123 (age) + 11.9 (sex) + 35.959 (lnBMI) [48].

Age = in years old at that time.

Sex = 0 for men and 1 for women.

InBMI = natural logarithm of the body mass index.

Cut-off points for obesity = men > 25%, women > 35%.

A previous study conducted by our research group demonstrated a high concordance (0.998) between ECORE-BF and the Clínica Universitaria de Navarra Body Adiposity Estimator (CUN-BAE), which is considered the gold standard for body fat estimation, as validated in a study published in *Diabetes Care* [49].

The risk of developing type 2 diabetes was evaluated using multiple validated predictive models:

- (1) FINDRISC: This index takes into account sex, age, BMI, waist circumference, physical activity, consumption of fruits and vegetables, use of antihypertensive medication, history of hyperglycemia, and family history of diabetes. A score higher than 15 indicates a high risk [50].
- (2) QDiabetes score (QD-score): This model incorporates variables including age, sex, ethnicity, height, weight, blood glucose levels, smoking status, history of stroke, family history of diabetes, use of antihypertensive medication, presence of depression or schizophrenia, and use of steroids or statins. It also considers a history of polycystic ovary syndrome or gestational diabetes. In the absence of established cut-off points, a relative risk of ≥3 was defined as indicative of a high-risk profile [51].
- (3) Canrisk: This index includes information on sex, age, physical activity, fruit and vegetable consumption, history of hypertension, past hyperglycemia, family history of

diabetes, ethnicity, and education level. A score above 43 suggests a higher diabetes risk [52].

- (4) Trinidad Risk Assessment Questionnaire for Type 2 Diabetes Mellitus (TRAQ-D): This model accounts for age, sex, BMI, smoking history, family history of diabetes, and ethnicity [53].
- (5) Prediabetes risk scale for Qatar (PRISQ Scale): This tool assesses prediabetes risk, incorporating factors such as age, sex, waist circumference, BMI, and blood pressure. In the Qatari population, a score ≥16 indicates a high risk, a threshold that was also found to be valid in the Spanish population [54].

With respect to the smoking status, individuals were classified as smokers if they had smoked at least one cigarette per day (or an equivalent tobacco intake in other forms) or had quit smoking within the last year.

The classification of workers by socioeconomic status was based on the 2011 Spanish National Occupational Classification (CNO-11) and the criteria established by the Spanish Society of Epidemiology's Social Determinant Groups: Class I (directors/managers, university professionals, athletes, and artists), Class II (intermediate occupations and selfemployed workers without employees), and Class III (unskilled workers) [55].

### 2.3. Statistical Analysis

A descriptive statistical analysis was performed by calculating the frequency and distribution of categorical variables. Since the quantitative variables followed a normal distribution, means and standard deviations (SDs) were computed. For comparisons between independent groups, Student's t-test was applied to continuous variables, while the Chi-square test was used for categorical data. Fisher's exact test was conducted when necessary. Receiver operating characteristic (ROC) curve analysis was utilized to assess the discriminatory power of ECORE-BF in predicting type 2 diabetes and prediabetes. The optimal cut-off values were determined mathematically from the ROC curves. All statistical analyses were conducted using IBM SPSS Statistics v29.0 for Windows, with a significance level set at p < 0.05.

#### 3. Results

Table 1 presents the clinical and demographic characteristics of the study population. In general, men exhibited higher or less favorable values for most anthropometric, clinical, and biochemical parameters.

The predominant age group among participants was 30–49 years, and the majority of workers belonged to social class III according to the established classification. Approximately one-third of the participants were identified as current smokers.

	Men	Women	Total	
	n = 246,061	n = 172,282	n = 418,343

ECORE-BF Córdoba Equation for Estimating Body Fat. QD-score Q diabetes score. TRAQ-D Trinidad Risk Assessment Questionnaire for Type 2 Diabetes Mellitus. PRISQ Prediabetes risk in Qatar.

As shown in Figure 2a,b and Table 4, the ECORE-BF scale serves as a strong predictor of high values in diabetes and prediabetes risk scales, as indicated by the areas under the curve (AUCs). The AUC values are particularly high for a QD-score > 3, specifically 0.970 (95% CI: 0.969–0.971) for men and 0.976 (95% CI: 0.975–0.977) for women. Additionally, the AUC values remain high across all other diabetes and prediabetes risk scales. In the diabetes risk scales, the AUC values are higher in women, whereas for prediabetes risk scales, they are slightly higher in men.

**Figure 2.** (a). ROC curves to estimate the value of ECORE-BF for predicting a high risk of prediabetes and diabetes in men. (b). ROC curves to estimate the value of ECORE-BF for predicting a high risk of prediabetes and diabetes in women.

### 4. Discussion

In our study, the ECORE-BF scale has demonstrated a high predictive value for identifying elevated values in different T2D and prediabetes risk scales, particularly a high QD-score.

Obesity is a well-established risk factor for T2D [56] and prediabetes [57] due to its contribution to insulin resistance and pancreatic beta-cell dysfunction. However, the distribution and composition of adipose tissue, rather than mere excess weight, appear to play a crucial role in the development of metabolic disorders [58]. Although the body mass index (BMI) is widely used as an indicator of obesity, it does not distinguish between fat mass and lean mass, nor does it consider the regional distribution of adipose tissue [59].

In this context, the assessment of body fat, whether through objective techniques such as dual-energy X-ray absorptiometry (DXA) [60] or bioelectrical impedance analysis (BIA) [61]; magnetic resonance imaging (MRI) [62]; or validated estimation scales such as the ECORE-BF equation [63], plays a crucial role as it allows for a more precise characterization of obesity and its metabolic implications. This discussion explores the relationship between body fat, particularly visceral adiposity, and the risk of T2D and prediabetes, emphasizing findings obtained through both objective measurements and estimation scales. A concordance analysis was performed using Pearson's correlation coefficient to evaluate the relationship between bioimpedance (BIA) and the ECORE-BF formula. The obtained result was a value of 0.915, indicating a high correlation and strong agreement between both methods for measuring body fat.

The location and function of adipose tissue significantly influence metabolic outcomes. Subcutaneous adipose tissue (SAT), predominantly found in the gluteofemoral region, has been shown to have protective effects against metabolic diseases [64]. In contrast, visceral adipose tissue (VAT), which accumulates in the abdominal cavity and surrounds vital organs, is strongly associated with insulin resistance [65], inflammation [66], and an increased risk of diabetes [67].

VAT contributes to metabolic dysfunction through several mechanisms:

- 1. Increased lipolysis and free fatty acid release: VAT is more metabolically active than SAT and releases higher amounts of free fatty acids (FFAs) into the portal circulation, contributing to hepatic insulin resistance [68].
- 2. Secretion of pro-inflammatory cytokines: Visceral adipose tissue (VAT) generates inflammatory cytokines, including tumor necrosis factor-alpha (TNF- $\alpha$ ) and interleukin-6 (IL-6), which disrupt insulin signaling and contribute to a state of chronic lowgrade inflammation [69].
- 3. Ectopic fat accumulation: Excess visceral adipose tissue (VAT) can result in lipid accumulation in non-adipose tissues, such as the liver, muscles, and pancreas, further aggravating insulin resistance and beta-cell dysfunction [70].

Studies using MRI and DXA have consistently shown that the VAT volume correlates more strongly with insulin resistance and T2D risk than the total fat mass or BMI [71]. These findings underscore the importance of assessing the body fat distribution rather than relying solely on BMI-based obesity classification.

There are different objective techniques for evaluating body fat and its association with diabetes risk:

- Dual-Energy X-ray Absorptiometry (DXA). DXA is widely regarded as the gold standard for analyzing body composition, providing precise measurements of total fat mass, lean mass, and visceral fat [72]. Studies have shown that a higher VAT volume and lower lean mass, as measured by DXA, significantly predict T2D incidence, independent of BMI [73]. For example, a prospective cohort study involving more than 1800 adults found that individuals in the highest VAT tertile (measured by DXA) had a 3.5-fold higher risk of developing T2D compared to those in the lowest tertile [74].
- Magnetic Resonance Imaging (MRI) and Computed Tomography (CT). Both MRI and CT provide highly accurate evaluations of adipose tissue distribution, enabling differentiation between VAT and SAT [75]. Some studies using MRI have demonstrated that progressive VAT accumulation is a key predictor of impaired insulin sensitivity and T2D development [76].

Given the high cost and limited accessibility of DXA, MRI, and CT, several validated estimation scales have been developed to assess body fat and its distribution. Among them, the ECORE-BF scale has been validated against reference methods and provides a reliable estimate of the body fat percentage [49].

Recent studies align with our findings and have demonstrated that the ECORE-BF scale exhibits a high predictive capacity for diabetes and prediabetes, with areas under the receiver operating characteristic (ROC) curve (AUC) exceeding 0.95 in both men and women [77].

The mean values and obesity prevalence, assessed using the ECORE-BF scale, were analyzed and stratified according to the risk levels in the diabetes and prediabetes scales. In both cases, it was observed that individuals classified as high-risk for developing diabetes or prediabetes had significantly higher obesity values compared to those classified in the lower-risk groups. These differences were consistent across both sexes and in the various risk categories, reflecting a strong relationship between obesity and metabolic risk. The results obtained were statistically significant, with a *p*-value < 0.001, highlighting the importance of obesity as a crucial risk factor in the prevention and diagnosis of diabetes and prediabetes. This finding underscores the utility of the ECORE-BF scale in identifying individuals at risk, facilitating early intervention.

Our results reveal that the ECORE-BF scale maintains a remarkable discriminatory ability across all the evaluated risk scales, not only for diabetes but also for prediabetes. Although the AUC values are high in both sexes, there is a trend in which women present higher AUC values in the diabetes risk scales, while in the prediabetes risk scales, the values are slightly higher in men. This pattern could reflect biological or metabolic differences between the sexes that affect the prevalence and progression of the disease.

These findings emphasize the relevance of the ECORE-BF scale as an assessment tool for the early identification of individuals at risk of developing diabetes or prediabetes, which could facilitate the implementation of personalized and effective prevention strategies, particularly in clinical and primary care settings.

The ECORE-BF scale was validated by comparing it with the CUN BAE (concordance index of 0.998 in over 196,000 people), demonstrating that it is as useful as this scale in the same populations, but its calculation is much simpler and requires far fewer parameters [78]. This scale has been validated in the Spanish population, suggesting its potential applicability in other European populations. However, since its formula includes lnBMI, we consider that its use in different ethnic groups and races requires adjustment of BMI cut-off points and prior validation in each specific population. In particular, the Asian population generally has a lower BMI but a higher body fat percentage compared to the Caucasian population. For this reason, the standard threshold for defining obesity (BMI  $\ge$  30.0 kg/m<sup>2</sup>) is inadequate, as it does not accurately reflect their body composition and associated metabolic risk. To ensure its correct application in these populations, it is essential to establish specific thresholds adjusted to their anthropometric and metabolic characteristics. Additionally, further studies should be conducted to validate the scale in other populations with different adiposity profiles and cardiovascular risk levels [79].

#### Strengths and Limitations

One of the main strengths of this study is its large sample size, along with the comprehensive evaluation of type 2 diabetes and prediabetes risk, incorporating analyses from five different assessment scales.

Additionally, since the participants were drawn from nine autonomous Spanish communities with substantial populations, the findings may be considered representative of the Spanish population.

Among the main limitations, this study lacks direct body fat measurements, relying instead on estimates derived from a validated scale. Moreover, the cross-sectional design limits the ability to establish causal relationships, allowing only for the identification of associations.

Another limitation is the exclusion of unemployed individuals, retirees, and those under 18 or over 69 years old. However, given the large sample size, these exclusions are unlikely to significantly affect the validity of the results.

The ECORE-BF formula has been validated for the Spanish population, and to apply it to other ethnicities or races, appropriate adjustments must be made.

In the female population, depending on individuals' hormonal statuses (pre- or postmenopausal), there are differences in how fat is deposited in the body and how the diabetes risk grows. Since we did not know the participants' dates of menopause onset, a corresponding adjustment could not be made.

## 5. Conclusions

Although obesity is a major risk factor for the development of T2D and prediabetes, the adipose tissue composition and distribution are more determinant than the total body weight or BMI. Objective measurements such as DXA, MRI, and BIA have demonstrated that visceral adiposity is a central factor in metabolic dysfunction.

Additionally, body fat estimation scales such as ECORE-BF provide a cost-effective alternative for predicting the T2D and prediabetes risk in large populations.

Future research should focus on longitudinal studies analyzing the impact of VAT reduction on diabetes prevention, as well as the integration of estimation scales into clinical practice and public health strategies.

**Institutional Review Board Statement:** This study was conducted in full accordance with the 2013 Declaration of Helsinki and established ethical research guidelines. Measures were implemented to ensure participant anonymity and confidentiality at all times. This study received approval from the Balearic Islands Research Ethics Committee (CEI-IB) under reference number IB 4383/20, approve date 2020-11-26. All participant data were coded, with only the principal investigator having access to identifiable information. Furthermore, all researchers involved in this study strictly complied with Organic Law 3/2018, enacted on 5 December 2018, which ensures the protection of digital rights and personal data. This legislation guarantees participants the right to access, modify, revoke, or object to the use of their personal data at any stage of the research.

**Informed Consent Statement:** Informed consent was obtained from all subjects involved in this study.

**Data Availability Statement:** The original contributions presented in this study are included in the article. Further inquiries can be directed to the corresponding author.

Conflicts of Interest: The authors declare no conflicts of interest.
